(Dated: May 4, 2009)

We examine the influence of coupling between particle-hole and particle-particle spin fluctuations on the inelastic neutron scattering resonance (INSR) in cuprate superconductors in both weak and strong interaction limits. For weak-interactions in the particle-hole channel, we find that the interchannel coupling can eliminate the resonance. For strong interactions which drive the system close to a $\boldsymbol{Q} = (\pi, \pi)$ magnetic instablity, the resonance frequency always approaches zero but its value is influenced by the interchannel coupling. We comment on constraints imposed on cuprate physics by the INSR phenomenology, and a comparison between the cuprates and the newly-discovered iron pnictide superconductors is discussed.

PACS numbers:

I. INTRODUCTION

The low-temperature properties of cuprate superconductors seem to be well described by mean-field-theory with effective interactions which lead to d-wave superconductivity, except possibly in the extreme underdoped limit. At the same time the apparently ubiquitous[1] presence of a low-frequency spin-resonance near $\boldsymbol{Q} = (\pi, \pi)$ in inelastic neutron scattering experiments and the appearance of spin order in some systems[2] when an external magnetic field is applied, suggest that superconducting cuprates are close to an antiferromagnetic instability. In previous work[3] we have argued that coupling[4] between particle-hole and particle-particle spin fluctuations likely contributes to the suppression of the superfluid density[5] observed in underdoped cuprates. In this article we specifically address, within time-dependent mean-field theory, the influence of particle-particle to particle-hole coupling on the inelastic neutron scattering resonance (INSR) position. When the interchannel coupling is ignored[6] an arbitrarily weak particle-hole channel interaction will induce a resonance. We find that the interchannel coupling can eliminate weak-interaction resonances. For stronger interactions the system can be driven close to an antiferromagnetic instability. In this limit we find that the way in which the resonance frequency approaches zero is influenced by the interchannel coupling. There is no limit in which RPA-type theories without the interchannel coupling yield reliable resonance frequency predictions.

II. RELATIONSHIP BETWEEN THE DIAGONAL AND OFF-DIAGONAL RPA SUSCEPTIBILITIES

In time-dependent mean-field theory the most general linear response of a system consists of correlated particle-hole and particle-particle excitations. For square-lattice models with on-site and near-neighbor electron-electron interactions we have shown previously[7] that at $\boldsymbol{Q} = (\pi, \pi)$ correlations occur between between four different weighted particle-hole transition sums. The most general response function can therefore be evaluated by inverting four by four matrices. For a model (motivated by the cuprate superconductivity literature) with only on-site (U) and near-neighbor (V) spin-independent interactions and nearest-neighbor Heisenberg (J) spin interactions we find[7] that:

$$\hat{\chi}^{-1}(\vec{Q},\omega) = \hat{\chi}^{-1}_{qp}(\vec{Q},\omega) - \hat{V} \tag{1}$$

where $\hat{V} = \mathrm{diag}(-U-2J, J/2-2V, V+J/4, V+J/4)$ is the interaction kernel,

$$\hat{\chi}_{ab,qp}(\vec{Q},\omega) = \frac{1}{N}\sum_{\vec{k}} \left(\frac{f_a(\vec{k}) f_b(\vec{k})}{\omega - E(\vec{k}) - E(\vec{k}')} - \frac{(-1)^{a+b} f_a(\vec{k}) f_b(\vec{k})}{\omega + E(\vec{k}) + E(\vec{k}')} \right) \tag{2}$$

is the bare mean-field-quasiparticle response function, and $\vec{k}' = \vec{k} + \vec{Q}$ reduced to the first Brillouin-zone. The indices a and b refers to the four coupled two-particle excitation channels and f_a is the corresponding coherence factor defined in Ref. [7]. As shown in previous work[7] the INSR mode is dominated by two channels, the spin flip ($a = 1$) and the d-wave pair phase ($a = 4$) modes, when parameters are in a range broadly consistent with experiment. The same conclusion can be reached on the basis of earlier approximate RPA theories[8] which omitted the second channel. The qualitative discussion of INSR physics below is based on a model in which only these two modes are retained, although the full 4-channel model is required for quantitative accuracy.

In the truncated two-channel model the INSR solves

$$K^s(\omega) K^\phi(\omega) = C^2(\omega)\omega^2 \tag{3}$$

where $K^s(\omega) = K^s_{qp}(\omega) - V_s$, $K^\phi(\omega) = K^\phi_{qp}(\omega) + V_\phi$, $V_s = U + 2J$, $V_\phi = V + J/4$, and the frequency-dependent stiffness and Berry-phase coupling parameters are defined by:

$$K^s_{qp}(\omega) \;=\; -\frac{1/\chi_{11,qp}(\omega)}{1 - R(\omega)}$$

$$K^{\phi}_{qp}(\omega) = -\frac{1/\chi_{44,qp}(\omega)}{1-R(\omega)}$$
$$C(\omega) = \frac{-1}{\omega}\frac{\chi_{14,qp}(\omega)}{\chi_{11,qp}(\omega)\chi_{44,qp}(\omega)(1-R(\omega))}$$
$$R(\omega) = \frac{\chi^2_{14,qp}(\omega)}{\chi_{11,qp}(\omega)\chi_{44,qp}(\omega)}. \quad (4)$$

$K^s(\omega=0)$ and $K^{\phi}(\omega=0)$ are[3] proportional to the energetic cost of static spin-density and spin-polarized electron-pair density fluctuations, as estimated by mean-field-theory while $C(\omega=0)$ is[3] the Berry-curvature associated with adiabatic evolution of electron-electron and electron-hole pair mean-fields. Stability of the d-wave superconducting state requires that both $K^s(\omega=0)$ and $K^{\phi}(\omega=0)$ be positive. In the two-channel approximation the interchannel coupling is captured by the function $\chi_{14,qp}(\omega)$. If $\chi_{14,qp}(\omega)$ was negligible, Eq. 3 would be satisfied at both the spin-exciton resonance frequency ω_{ex} defined by

$$1/\chi_{11,qp}(\omega_{ex}) + V_s = 0, \quad (5)$$

and at the π-resonance frequency ω_{π} defined by

$$1/\chi_{44,qp}(\omega_{\pi}) - V_{\phi} = 0. \quad (6)$$

When coupling between particle-hole and particle-particle channels is neglected both $R(\omega)$ and the Berry phase coupling $C(\omega)$[3,7] are set to zero. It is therefore important to study how $R(\omega)$ and $C(\omega)$ depend on the model parameters. Since both R and C are dimensionless, the unbiased justification of whether or not the interchannel coupling is negligible should be based on these two quantities. It is evident from the definition of $R(\omega)$ and from the way in which it appears in the above equations, that the interchannel coupling certainly can not be neglected when it approaches 1. To judge the importance of the Berry-phase coupling $C(\omega)$, we should compare $|C| \times \omega_{res}$ with typical values for $\sqrt{K_s \times K_{\phi}}$, which indicates that values of $|C|$ comparable to 1 also correspond to strong interchannel coupling.

The mean-field-theory of INSR is defined by the hopping parameters of the square-lattice tight-binding model and by the interaction parameters U,V, and J. We emphasize that all these parameters should be viewed to a large degree as effective parameters which depend on microscopic many-body physics in ways which are not fully understood. Their values are therefore best determined phenomenologically. Luckily the quantities $R(\omega)$ and $C(\omega)$ depend only on the normal state band-structure model, and on the maximum of the mean-field d-wave energy gap Δ. At the current mature state of cuprate experimental research, the information we require is therefore available with adequate accuracy.

Fig. 1(a) plots $R(\omega)$ for $\omega \leq \Omega_0$, where Ω_0 is the minimum two-particle excitation energy, with two very different band structures. Fig. 1(b) plots $C(\omega)$. Although the association of C with Berry phases is not strictly appropriate away from the adiabatic limit, it is appropriate to

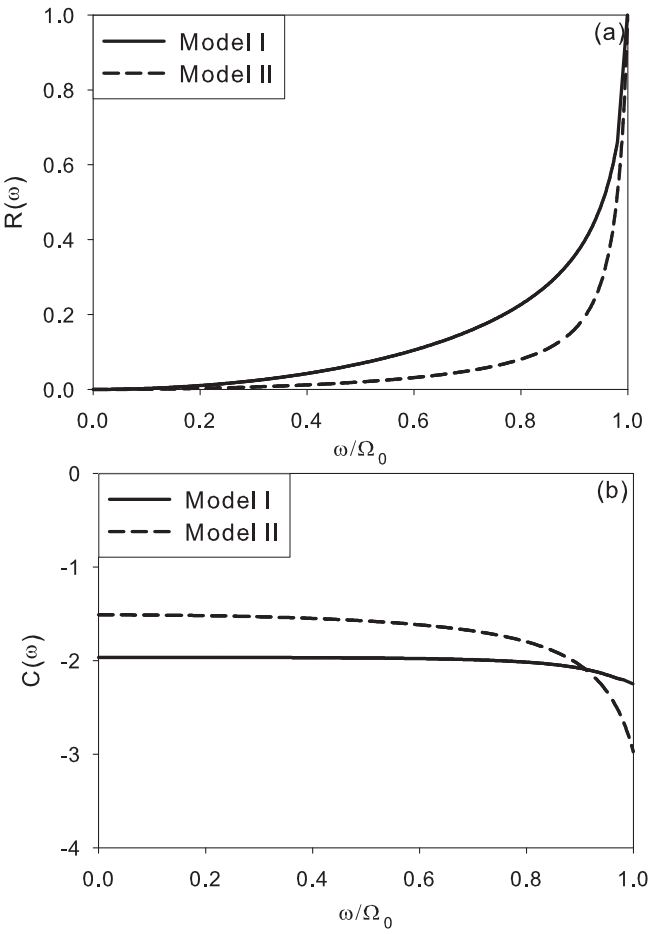

FIG. 1: (a) $R(\omega)$ and (b) $C(\omega)$ for two difference band structures. $\Omega_0 \sim 70$ meV in both models. The property that $R(\omega)$ approaches 1 for $\omega \to \Omega_0$ is a universal feature which applies for any band structure model. $C(\omega)$ is finite and large in both models.

retain the terminology because $C(\omega)$ has weak frequency dependence up to quite high frequencies. Model I in Fig. 1 refers to the band structure model obtained by Norman *et al.*[11] by fitting to angle-resolved-photoemssion data[9] and used by us in our previous work[7]. Model II refers to a model used by Hao and Chubukov[10] in a related recent work. The main difference between these two models is that the nearest-neighbor hopping t is almost 2.5 times bigger in Model II than that in Model I. Since the maximum energy gaps in both models are fitted to be around $35-50$ meV in the underdoped regime, the ratio of the energy gap to the kinetic energy is much smaller in Model II than that in Model I. This difference is responsible for the generally weaker interchannel coupling effects seen in both the $R(\omega)$ and $C(\omega)$ in Model II as shown in Fig. [1]. We note however that $R(\omega) \to 1$ as ω approaches Ω_0 in both models, and indeed as we discuss below, for any band-structure model. Although Model I seems to be much more sophiscated and better fitted with

experiments[11], we study both models to ease comparison with Ref. [10] and to provide some quantitative indication of the sensitivity of our conclusions to very-different band-structure model choices.

III. WEAK INTERACTION LIMIT

Weak interactions can compete with band energies for ω smaller than but close to the minimum two-particle excitation energy Ω_0 because the energy denominator in Eq. 2 becomes small when $\boldsymbol{k}$ approaches $\boldsymbol{p}$, the point at which $E(\vec{k}) + E(\vec{k'})$ is minimized. By expanding the energy denominator around its minimum we find that all elements of the quasiparticle response function diverge logarithmically as $\omega \to \Omega_0$ from below:

$$\begin{aligned}\chi_{11,qp}(\omega = \Omega_0^-) &\sim f_1^2(\vec{p})\ \nu_0 \ln(1-\omega/\Omega_0)\\ \chi_{44,qp}(\omega = \Omega_0^-) &\sim f_4^2(\vec{p})\ \nu_0 \ln(1-\omega/\Omega_0)\\ \chi_{14,qp}(\omega = \Omega_0^-) &\sim f_1(\vec{p}) f_4(\vec{p})\ \nu_0 \ln(1-\omega/\Omega_0). \quad (7)\end{aligned}$$

Here ν_0 is the joint density of states per site just above the minimum excitation energy. Note that all off-diagonal elements of the quasiparticle response matrix approach the geometric mean of the corresponding diagonal elements, so that the response matrrix becomes singular and $R(\omega = \Omega_0^-) \to 1$. As we explain below, the familiar BCS-like weak-interaction result for the spin-exciton resonance frequency is qualitatively altered as a consequence.

When the interchannel coupling is neglected, the spin exciton energy ω_{ex} is obtained[6] by inserting Eq. (7) in Eq. (5) to obtain

$$1 - \frac{\omega_{ex}}{\Omega_0} = \exp\Big(-\frac{1}{\nu_0 V_s f_1^2(\vec{p})}\Big) \quad (8)$$

An undamped resonance appears just below the two-particle continuum edge for an infinitesimally small positive V_s. To account for the interchannel coupling for ω near Ω_0 we rewrite Eq. (3) as

$$(-\chi_{44,qp}(\omega) - D(\omega)V_s)(-\chi_{11,qp}(\omega) + D(\omega)V_\phi) = \chi_{14,qp}^2 \quad (9)$$

where

$$D(\omega) = (\chi_{11,qp}(\omega)\chi_{44,qp}(\omega) - \chi_{14,qp}^2(\omega)). \quad (10)$$

Note that, although each matrix element diverges logarithmically the geometric product structure of the matrix implies that $D(\omega)$ diverges like ln, not like $\ln^2$. After some algebras, we obtain

$$1 - \frac{\omega_{INSR}}{\Omega_0} = \exp\Big(\frac{-1}{\nu_0(V_s f_1^2(\vec{p}) - V_\phi f_4^2(\vec{p}))}\Big). \quad (11)$$

If $V_\phi > 0$, V_s must be greater than a critical value in order to have a resonance and $\omega_{INSR} > \omega_{ex}$ in agreement with Ref. [10]. If $V_\phi \leq 0$, $\omega_{INSR} \leq \omega_{ex}$ and an infinitesimal positive V_s is again sufficient to guarantee a resonance below the two-particle continuum.

IV. STRONG INTERACTION LIMIT

Strong interactions drive the system close to the antiferromagnetic instability, *i.e.* into the regime which appears to be relevant for optimally doped and moderately underdoped cuprates. Given the instability criterion, $K^s(\omega = 0) = K^s_{qp}(\omega = 0) - V_s$ with $V_s = U + 2J$ we see that either on-site Coulomb interactions U, or Heisenberg near-neighbor spin-dependent effective interactions J, or a combination of the two, could be responsible. Since, as we mention again below, experiments imply that $K^s(\omega = 0)$ is around an order of magnitude smaller than $K^s_{qp}(\omega = 0)$, the value of V_s is tightly constrained on a relative basis. It has been argued[10] that ω_{ex} should match ω_{res} accurately in a relative sense in this limit because the frequency which appears in the Berry phase coupling term is small. As we will prove in detail later, this argument is not necessarily correct because the leading frequency dependent term in the low-frequency expansion of Eq.3 varies as ω^2, and all ω^2 terms, including the Berry phase coupling term, should be retained.

Let's consider the case in which the system is close to the antiferromagnetic instability so that the INSR frequency is small. We expand the quasiparticle-response dependent quantities at low frequencies as follows: $\chi_{11,qp}(\omega) \approx -(R_0^s + R_2^s\omega^2)$, $\chi_{44,qp}(\omega) \approx -(R_0^\phi + R_2^\phi\omega^2)$, $R(\omega) \approx R_{14}\omega^2$, and $C(\omega) \approx C$. Detailed expressions for the positive-definite coefficients $R_0^{s,\phi}$, $R_2^{s,\phi}$ and R_{14} can be found in Ref. [7]. R_{14} and C are related by $C = R_{14}/\mathcal{D}$ where $\mathcal{D}$ is the low frequency limit of $\chi_{14,qp}(\omega)/\omega$. The spin-exciton energy can be obtained by setting $V_s\chi_{11,qp}(\omega) = -1$. We find that

$$\omega_{ex} = \sqrt{\frac{1 - R_0^s V_s}{V_s R_2^s}} \equiv \sqrt{\frac{\delta}{V_s R_2^s}}, \quad (12)$$

where δ is defined by the second equality. The above expression is valid close to the antiferromagnetic instability, *i.e.* for $\delta =\to 0^+$. When the interchannel coupling is included the corresponding resonance energy ω_{INSR} expression is obtained by solving Eq. 3 retaining terms up to order ω^2. After some algebras we find:

$$\frac{\omega_{INSR}}{\omega_{ex}} = \frac{1}{\sqrt{1 + \gamma_1 + \gamma_2}} \equiv \gamma \quad (13)$$

where

$$\gamma_1 = \frac{D^2}{R_0^\phi R_2^s}\left(\frac{1}{(1-\delta)(1 + V_\phi R_0^\phi)} - 1\right) \quad (14)$$

and

$$\gamma_2 = \frac{-\delta(R_2^\phi - R_0^\phi R_{14})V_\phi}{(1 + V_\phi R_0^\phi)R_2^s V_s}. \quad (15)$$

Since $\gamma_2 \propto \delta \to 0$ near the spin-density instability, the discrepancy between ω_{INSR} and ω_{ex} is mainly associated with the parameter γ_1. We comment further on this point in the next section. Clearly the value of γ_1 depends strongly on model parameters.

V. DISCUSSION

As emphasized in our previous work[7], because we have three interaction parameters (U, V, J) but only two experimentally-determined properties, the anti-nodal gap and the INSR frequency, experiment does not uniquely determine the effective interaction model. The two combination of interaction parameter combinations that are tightly constrained by experiment are the spin-interaction $V_s = U+2J$ (INSR experiment) and the pair-potential $V_{pair} = 3J/2-2V$ (ARPES and other measures of the d-wave antinodal gap). We have argued previously that the $V = 0, J \neq 0$ (J-scenario) possibility (pairing driven by effective Heisenberg interactions) is more likely than that $V \neq 0, J = 0$ (V-scenario) possibility (pairing driven by attractive scalar near-neighbor interactions). Our argument appealed to the *Occam's razor* assumption that one type of effective interaction is likely to play a dominant role in the low-energy physics. We then observed that the J-scenario can account for both V_s and V_{pair} scales whereas the V-scenario requires in addition a finely-tuned on-site effective interaction. (U would have to be at least $350meV$ in model I and 800meV in model II if the V-scenario was adopted to fit the experimental data[7,10].) It is in fact clear from the outset that the near-neighbor scalar interaction V cannot succeed in accounting for both scales because it contributes to V_{pair} but not to $V_s = U + 2J$. On the other hand, the J-scenario is not trivially guaranteed to explain both experimental energy scales. This fact does appear to us to be strongly suggestive.

Eqs. (13,14,15) demonstrate that interchannel coupling can alter the resonance frequency even in the limit $K_s \to 0$ and that the resonance frequency always depends on both V_ϕ and V_s. In the J-scenario we favor V_ϕ is small and positive, and γ_1 tends to be negative in models which are close to the antiferromagnetic instability. For this reason γ is slightly larger than 1 in both models we have examined. For Model I, we find $\gamma \approx 1.1$ while for Model II we find $\gamma \approx 1.04$. The approximate coincidence between ω_{ex} and ω_{INSR} for some model parameters does not imply that particle-hole and particle-particle modes are weakly coupled in the elementary excitations. In fact, it is evident in Fig. (1) that $C(\omega)$ is weakly frequency dependent and remains comparable to 1 in both models, which already guarantees the strong interchannel coupling as discussed above. The close match between ω_{ex} and ω_{INSR} only reflects that the choice of interaction parameters leads to not only $K^s(\omega) \to 0$ (i.e. $\delta \to 0$) but also the large ratio of $K_\phi(\omega)/K_s(\omega)$ at low frequency. For realistic experimental situations in which the resonance frequency is always a substantial fraction of the antinodal gap, this ratio is always larger than approximately 3, which does favor $\omega_{INSR} \approx \omega_{ex}$. This analysis proves that the ratio of $\omega_{INSR}/\omega_{ex}$ can not serve as a reliable criterion to judge the importance of the interchannel coupling. We have referred to this resonance as a magnetic plasmon to suggest this aspect of its character, namely that it represents the coupled quantum fluctuations of canonically conjugate degrees of freedom as long as $|C|$ is comparable to 1. Our conclusions on this point are in disagreement with those of Ref. [10].

In Ref. [3] we have argued that the quantum zero-point energy of cuprates makes a negative contribution to the superfluid density of cuprates, and that it therefore contributes to the decrease of the critical temperature in the underdoped regime. The basic idea is that superconductivity is weakened by phase gradients, allowing the antiferromagnetic instability to creep closer and reducing the quantum zero-point energy associated with spin-fluctuations. Similar physics occurs in bilayer quantum Hall superfluids[12,13]. Microscopic caclulations suggest that in cuprates this effect is large enough to account for the decreasing superfluid density, in contrast to the situation in typical superconductors in which correlation effects are largely independent of the configuration of the superfluid condensate. It will be interesting to examine how this idea plays out when applied to the recently-discovered iron pnictide superconductors. Current experiments and theories seem to favor extended-s-wave gap symmetry. An INSR has been observed[14,15,16] in the pnictide materials with a phenomenology which is surprisingly similar to that of the cuprates. Because the the ratio $2\Delta/k_BT_c$ is found to be remain close to the BCS predcition[17], it seems that the supression of superfluid density by correlations is less important in this material. To account for this difference within our theory, we will need to understand why phase gradients in the superconducting condensate have a weaker effect on spin-fluctuations and on the correlation energy. The multi-band character and the peculiar Fermi surface pockets of pnictides would seem likely to produce this result. The large effect in cuprates rests strongly on the importance of fluctuations near the wavevector which connects anti-nodal momenta for spin-response functions, a coincidence that is not likely to be repeated in iron pnictide superconductors. A recent RG analysis[18] which showed that the particle-hole and particle-particle channels are decoupled at energy scalies below the Fermi energy E_F supports this view. A more detail calculations for the iron pnictides using an appropriate multiband model which aims to resolve this issue is currently in progress.

Based on these analyses, we conclude that Berry phase coupling between the particle-hole and particle-particle channels can never be ignored in any RPA-type theory of the inelastic neutron scattering resonance mode for cuprates. As a result, the inelastic neutron scattering resonance mode observed in cuprates should be bettter interpreted as a magnetic plasmon than a spin exciton. The importance of coupling in the pnictides has not yet been adequately analyzed. Nevertheless, the spin resonance mode observed in the inelastic neutron scattering measurements could be a purer spin exciton, and the magnetic and superconducting instablities less coupled in the pnictide case.
